

$$c <$$

Hello

Theory In this section we consider the simplest model that captures the essence of non-hermitian behaviour: 2 linear

$$\ddot{y} + k_0 y + \gamma \dot{y} + k_c y^3 - k_a x = 0 \text{ [should I add nonlinear cubic term to stabilize??] where } k_0 \text{ is the harmonic bound strength}$$

$$counterclockwise : E_2 = \frac{i}{2} \left(-\gamma + \frac{k_a}{\sqrt{k}} \right) \text{ and the eigenvectors are } \text{ clockwise } v_1 = \begin{pmatrix} 1 \\ -i \end{pmatrix}$$

$$-i$$

$$counterclockwise v_2 = \begin{pmatrix} 1 \\ i \end{pmatrix}$$

i. On the one hand, E_1 has 2 eigenvectors in which the oscillator rotates clockwise in the plane. What distinguishes the

By plotting the trajectory of the system in state space, i.e. in the x - y plane, we can see the effect of the non-reciprocity

In conclusion, we use odd elasticity (or non-reciprocity in general) between two linear actuators to achieve stable linear

Experiments

The regime below the Hopf bifurcation, where the system goes to rest, is not interesting, so we focus on the regime above
